ABSTRACT
Operators of plants, facilities, and pipelines have at their disposal multiple resources for evaluating the integrity of identified features and anomalies. With advances in inspection technology, industry is being called upon to evaluate an ever-increasing number of features. When a feature is identified as a threat and severe enough to warrant repair or replacement, operators are faced with sometimes significant costs.

In this paper the authors provide guidance on the benefits associated with full-scale testing for evaluating mechanical integrity, referred to Intentional Destructive Testing (IDT). Unlike many analysis techniques that require the development and implementation of assumed operating and boundary conditions, well-designed IDT programs are able to replicate in situ conditions to provide operators with a clear understanding regarding the behavior of anomalies and their response to simulated operating conditions. Case studies are included to demonstrate the merits of the IDT approach. In using IDT, operators have improved confidence in predicting the behavior of identified features to ensure that maintenance resources are properly allocated for either continuing operation or repairing anomalies.

NOMENCLATURE
FEA  Finite element analysis
IDT  Intentional destructive testing
ILI  In-line inspection tool
IMP  Integrity Management Program
MAOP Maximum Allowable Operating Pressure
SMYS Specified Minimum Yield Strength

INTRODUCTION
At the core of integrity management is the need to ensure the safe operation of pipeline systems. There are obviously numerous means for addressing the needs associated with this central requirement, several of which include studying historical trends and failure patterns, numerical modeling, and full-scale testing. From a statistical standpoint, as the age of a given pipeline increases the likelihood for deterioration of the system also increases. As a result, the importance of understanding the present and future behavior of an aging pipeline becomes even more critical.

In recent days the authors have observed an increased interest in pipeline operators requesting that full-scale testing be performed to predict future performance of pipeline materials and existing anomalies such as dents in welds, wrinkle bends, crack-like flaws in seam welds, pipe fittings such as wyes, elbows, and branch connections, and vintage girth welds. The central driver behind this trend is that operators need to assess the integrity of their pipeline system in a manner that cannot be achieved using an analysis-only (i.e. numerical modeling) approach. The consequence of failure for transmission pipelines is too high to risk the potential for errors and possible lack of conservatism associated with unknowns in a numerical model. In a similar manner, analyses methods that are overly-conservative will generate unnecessary remediation activities. This is likely to create other problems such as over-digging and not focusing on the major problems in a pipeline.

A well-organized and executed testing program can provide significant insights into the performance of a pipeline, both present and future. As part of this effort, readers are encouraged to consider the following benefits in pursuing testing as a means for evaluating mechanical integrity.

- It is possible to organize a testing program that represents future service conditions for a pipeline. As an example, one can apply pressure cycles to a given sample to represent 20 years of future service prior to performing a burst test on a known flaw. In this manner, the testing organization is able to provide the operator with a snapshot of how their pipe material might perform at some future date.

- Most analyses required some consideration of a range of input variables, typically involving material properties and behavior. Because of the potential for variability at the input level, one must bound analysis problems to ensure that both the upper and lower bound responses have been captured. This invariably leads to reduced confidence in results. If one is to integrate selected tests into a study of this type, the overall uncertainty of the analysis work is reduced and greater confidence in predicting the behavior of the pipe is achieved when using numerical models.

- Testing can also be used to validate numerical models and improve confidence in analysis results. Typically, several well-designed tests can accompany a wide range of numerical models.

The purpose of this paper is to provide guidance for the pipeline industry in how testing, primarily full-scale destructive testing, can enhance and improve integrity management efforts. The organization of this paper includes discussions on testing methods, types of testing, case studies based on prior work, integrating analysis and testing results, and lastly a discussion on guidance in using testing as part of an engineering-based integrity management program.
TYPES AND METHODS OF TESTING

In order to discuss the value in testing it is obviously important to consider types of testing and how they are used to evaluate pipeline performance. The sections that follow include discussions on the following types of tests:

- Burst tests
- Cyclic pressure testing
- Bend testing
- Simulated damage creation

Discussions include how the tests are performed (i.e. testing methods) and what is learned in performing each test. On occasion different tests are combined to better represent actual service conditions. An example is to subject a pipeline test sample to cyclic pressures for a specified number of cycles (e.g. number of cycles representing a 20 year service life) prior to performing a burst test. This in effect provides a snapshot of the future burst capacity of the pipeline corresponding to the designated future service period.

Burst Tests

As the name implies, burst tests involve taking a test sample all the way to failure due to pressure overload. The benefit in doing so is to determine the ultimate pressure capacity of a given piece of pipe. Of equal importance is to determine the reduction in strength associated with given defects such as a crack-like flaw in a seam weld or a plain dent with corrosion.

Prior to going to failure, it is often beneficial to perform pressure holds at levels corresponding to the operating pressure of the pipeline as well as the pressure associated with the SMYS. Strain gages are also useful for providing strain in anomalies such as corrosion or a dent.

Pressure Cycle Fatigue Testing

Over the years the authors have performed hundreds of pressure cycle tests. Often the purpose in testing has been to destructively test a sample via fatigue having known defects or flaws. Another trend that has been frequent as of late is the use of pressure cycling to introduce cumulative damage prior to actually performing a burst test. This is a useful and powerful technique for providing an operator with a rainflow counting technique to develop a single equivalent pressure range (details provided in discussion below) using actual pressure data from a compressor or pump station. Both cycle counting (e.g., rain-flow) and a damage rule (e.g., Miner’s Rule) are required to define a single equivalent pressure range. The random nature of the actual pressure data can be converted into a single equivalent pressure range that can then be applied to the pipe sample during testing. Consider the table provided in Figure 2 a 4th order relationship is assumed between stress and cycles as expressed in the following relation based on Miner’s Rule.

\[ N_{AP} = N_{1140} \left( \frac{1140 \text{ psi}}{\Delta P} \right)^4 \]  

In this equation \( N \) is the number of respective cycles and \( \Delta P \) is the applied pressure range in units of psi. For each pressure range captured from the rainflow counting exercise (and shown in the histogram in Figure 2) a new equivalent cycle number is generated assuming an alternating pressure of 1,140 psi (7.9 MPa) pressure range. As noted in this table provided in Figure 2, the sum of all resulting cycles generates a single equivalent pressure cycle. Therefore, from the random pressure data presented in Figure 1, a single equivalent cycle number of 69 is generated assuming an alternating pressure of 1,140 psi (7.9 MPa) as presented in the table in Figure 2.

Bend Testing

Bending is always part of offshore pipeline work, whether it is at the installation level or subsea accounting for responses to operating loads such as thermal buckling; however, bending can also be an issue for onshore pipelines when considering the effects of terrain, land movement, earthquakes, and mudslides. In addition to introducing bending loads, tests can simultaneously introduce the effects of internal pressure and axial tension or compression.

Because of safety concerns, bending tests often do not involve testing to rupture. Rather, bending loads are applied until a plastic collapse condition is reached and the limit state load is defined (i.e. the point where the pipe can take no more appreciable loading). Strain gages are typically used in bend testing to provide feedback on the level of strain introduced into the test sample and to identify the plastic collapse load. A case study is presented that provides results...
for a bend test used to quantify the level of reinforcement provided to
defective girth welds reinforced with composite materials.

Simulated Damage Creation

Although a fair portion of work performed by the authors and
their firm have involved testing actual defective pipe materials
removed from the field, efforts are also required to simulate damage
using laboratory means. Besides the obvious inclusion of applying
excessive loads during tests (i.e., pressure, tension, and bending) to
introduce failure, the defects most often simulated during testing
include corrosion, plain dents, and mechanical damage.

Figure 3 shows the set-up for testing done to generate
mechanical damage in 12.75-inch (324 mm) diameter pipe material.
To inflict damage a gauge was generated by forcing a back-hoe tooth
into the sample that was simultaneously pulled, during which
pressure was maintained in the sample at 70% SMYS. Figure 4
shows the geometry for the three back-hoe teeth as well as a
photograph of one of the simulated defects.

Whenever simulated data is created, it is important to ensure that
the damage imparted to the pipe is representative of actual conditions
as much as reasonably possible. This might require the use of
numerical modeling using either finite element analysis (FEA) or
fracture mechanics. An example is using FEA prior to indenting a test
sample to determine the geometry of an indenter needed to achieve a
certain dent profile.

CASE STUDIES

The best means for demonstrating the effectiveness of IDT as a
means for assessing mechanical integrity is providing several case
studies. The case studies included in this paper provided details on
studies actually conducted for pipeline operators. An important
consideration for the information presented herein is that several of
these case studies were used to convey to government regulators the
soundness of the pipeline in question. In effect these tests became
part of integrity management program packages that assisted
operators in defending their proposed courses of action.

The presentations that follow for each of the case studies contain
the following elements:
1. Purpose of test
2. Type of test
3. Implications of results.

Destructive Testing Vintage Pipe with Crack-like Features

As part of their integrity management program (IMP), an
operator of a 16-inch diameter propane pipeline identified the
presence of seam features during a magnetic flux leakage in-line
inspection run. Using a combination of fatigue and burst testing, the
pressure capacity of pipe material removed from service was
determined using three samples. Prior to burst testing, the test
samples were pressure cycled 3,100 times at a pressure range of 45
percent SMYS. Considering a moderately aggressive pressure
spectrum, this corresponds to approximately 20 years of service for
this particular pipeline system.

Of the three burst tests that were performed, the minimum burst
pressure that occurred was 2,129 psi, which corresponds to 148
percent of the yield pressure and translates to a hoop stress of 68,128
psi. Figure 5 is a photograph showing the hydrostatic test rupture in
Sample #1; note the location of the longitudinal seam weld that
occurred outside the failure. Table 1 lists the test pressure results for
all three burst samples.

Post-failure metallurgical evaluation showed that no failures
occurred in the weld seam and that none of the seam weld features
contributed to the pressure failures. Additionally, there was no
evidence that corrosion or fatigue contributed to the rupture origins or
that failures occurred due to deficiencies in material properties.

The implications for the operator of this propane pipeline
associated with the results of this study provided a framework for
making future decisions on the operation of this line. Additionally,
the consistent test results provided greater confidence in the proposed
continued operation of the line. Even though seam weld features were
identified by ILI, the test results showed that the magnitudes of burst
pressure were acceptable for the continued operation of the pipeline.
Furthermore, the pre-burst cycling effort provided the operator with a
“snapshot” of what future performance could be expected.

Reinforcement of Vintage Girth Welds

Girth welds are an essential part of every transmission pipeline.

With much of the current pipeline system in the United States having
been installed prior to 1970, concerns exist with some pipeline
companies regarding the integrity of vintage girth welds. While it is
true that the failure rate in the United States attributed to vintage girth
welds (based on information reported to the authorities) has not been
widespread, operators recognize that they cannot be complacent as
their infrastructure ages and that they should continue to search for
alternatives to conventional repair and replacement options that will
continue to ensure integrity.

For this reason, a study was conducted to evaluate the use of
composite materials in reinforcing girth welds. Co-participants in this
study included five composite repair manufacturers that currently
market products and systems for reinforcing pipelines with anomalies
and defects. These manufacturers made financial contributions,
donated materials, and provided personnel who completed repair
installations on their respective test samples.

The program involved the reinforcement of 12.75-inch x 0.188-
inch, Grade X42 pipe samples with defective girth welds that did not
include a root pass (i.e., simulated lack of penetration weld defects)
as shown in Figure 6. Each manufacturer was responsible for
repairing three pipe samples that included one tension-to-failure
sample, one tension-to-failure sample with a reduced bonding area,
and a bending-to-failure sample. Additionally, two unreinforced pipe
samples with defective girth welds were tested (i.e., tension-to-failure
and bending-to-failure samples) to provide a baseline data set to
which results for the reinforced samples could be compared.

Prior to the destructive tension and bending tests, all reinforced
samples were subjected to 18,000 pressure cycles ranging from 445
psi to 890 psi (36% SMYS to 72% SMYS). This condition
approximates a 20-year service life for gas pipelines, assuming an
aggressive pressure condition with 889 cycles per year at a stress
range of 36% SMYS. For each test to failure, an internal pressure of
445 psi (36% SMYS) was held constant during testing.

During bend testing, all five of the composite reinforced systems
performed well in the sense that the initial level of distortion in the
pipe occurred outside of the reinforcement. These results demonstrate that the stiffness of the reinforced sections are not only greater than the base pipe, but of sufficient magnitude to ensure that wrinkles form outside a composite-reinforced section when subjected to bending loads. Figure 7 includes photographs of the unreinforced bend sample, including a cross-section of the weld after failure. The sample shown in this figure was subjected to increasing bending loads until a failure occurred.

When considering the performance of the composite reinforcing systems, there were some differences in the results for the tension-to-failure samples. The unreinforced tension sample failed at a tension load of 293 kips. Considering the reinforced tension samples with full bonding areas, the reinforced samples had tension-to-failure loads ranging from 433 to 481 kips. The repair using Product C was able to achieve a maximum tension load of 522 kips with failure occurring in the base pipe near a welded bossset outside the repair, as shown in Figure 8. A plot of tensile load versus deflection for all five of the tested systems is shown in Figure 9. The results presented in this plot only include loads applied by the load frame; whereas the tension values presented above include the presence of pressure end loads.

The results of this program demonstrated that, when properly designed and installed, composite materials reduce hoop and axial strains in girth welds and increase the limit-state capacities under combinations of pressure, tension, and bending loads. Thus, these systems provide pipeline operators with a reinforcing method to improve the reliability and integrity of pipelines having defective girth welds.

**Burst Testing of Long Radius Elbow**

Questions were posed regarding the integrity of elbows purchased for use in a proposed jet fuel hydrant system. The system was expected to operate at a steady state pressure of 150 psi with maximum surge pressures of 50 psi (i.e. maximum expected pressure of 200 psi). A burst test was performed on a 16-in x 0.375-in, Grade WPB 90° long radius elbow. As shown in Figure 10, locations for seven strains gages were selected to maximize the number of measurements in the elbow, but also monitor strain in the attached piping. Figure 11 is a photograph the installed strain gage on the intrados of the bend.

The burst test included 5 minute pressure holds at 72% SMYS (1,181 psi) and 100% SMYS (1,640 psi). Strain gage readings were taken at a rate of 1 scan per second continuously during the duration of the test. After the two pressure holds, the test assembly was pressurized to failure where a maximum pressure of 3,094 psi was achieved. The failure in the test assembly did not occur in the long radius elbow, but took place in one of the attached pipe segments as shown in Figure 12. It appeared, based on strain gage readings, that the pipe material likely had a lower yield than the material used in the elbow.

The following observations were made in reviewing the strain gage results:

- The hoop strain readings at Locations #3 and #6 had the lowest recorded strains and were the last to demonstrate yielding. This is consistent with the mechanics for long radius elbows where hoop stresses at the extrados are 75% of the nominal hoop stress, whereas stresses in the intrados are 125% of the nominal value (assuming the same wall thickness for all regions).

- The strain readings for the intrados gages (Locations #1 and #4) are consistent in that they track together. It is also noted that above 2,500 psi internal pressure, the strains in the intrados are less than those measured along the elbow’s neutral axis (Locations #2 and #5) and the base pipe (Location #7); a fact noted due to the thicker intrados (i.e. the average thickness at the intrados was 11 percent more than the nominal elbow wall thickness of 0.375 inches).

Considering that a maximum pressure of 3,094 psi was reached in the test assembly, a safety factor of 15.5 exists on burst when assuming a maximum operating pressure of 200 psi. This program, although relatively simple to execute, was effective in confirming the integrity of the elbows in question and providing the operator confidence that the quality of the purchased elbows was sufficient for their intended service.

**ENGINEERING BASED INTEGRITY MANAGEMENT**

The prior discussion provides a good example of how analysis and testing can be integrated to provide improved confidence in analysis results. The greatest contribution when considering numerical modeling techniques is the development of grading tools for quantitatively assessing pipeline damage. At the present time there are several areas of interest for pipeline operators where the development of these types of tools will be of significant benefit. Figure 13 is a flow chart that shows the central elements involved in developing an Engineering-Based Integrity Management Program (EB-IMP). As noted, analysis and testing methods work hand-in-hand to facilitate the development of tools that can be used by operators to evaluate the level of criticality associated with a particular defect or anomaly.

Based on discussion with pipeline operators, there are several areas of concern that pose threats to the integrity of pipeline systems. A grading tool could be developed for each of the following defect types in association with an EB-IMP.

- Plain dents
- Dent in girth and seam welds
- Rock dents
- Vintage girth welds
- Seam welds (with detected crack-like flaws)
- Wrinkle bends
- Effects of composite materials in increasing the burst capacity and fatigue strength of any of the above

To ensure the validity of any tool that is developed, both analysis and testing are required. At the outset of any project whose intent is to develop a grading tool, it is essential that planning be conducted to maximize information gained from collected results. Of particular note is the fact that significant savings can be realized in conducting select tests to validate specific numerical models as opposed to conducting an extensive array of full-scale tests. Proper planning increases the likelihood that a useful grading tool will be developed.
CONCLUSIONS

This paper has provided details on how IDT full-scale testing methods can be used by pipeline operators to gain understanding about how pipelines respond to loading conditions that can lead to failure. By understanding how pipelines fail, operators are better-positioned to identify/understand which defects are of most concern and what margins of safety actually exist in operating a pipeline. While numerical modeling is useful for understanding the general response of pipe materials, it is unwise to solely rely on guidance based on analytical findings when the opportunity for full-scale testing is an option. As has been demonstrated herein, when tests are properly coordinated and planned, they can be used to validate numerical models and improve the overall confidence in grading tools.

In addition to validating numerical models, testing provides a powerful resource for assisting operators in predicting the future performance of pipelines. The most appropriate example based on information presented in this paper includes conducting full-scale burst tests on pipe samples that have been previously pressure cycled to simulate future service conditions.

It is hoped that the information in this paper will encourage and foster additional discussions among those in the pipeline industry. Because of the critical role that pipelines have in terms of the worldwide energy infrastructure, significant benefits are derived in conducting tests as part of an engineering-based integrity management program.
